Abstract

According to the WHO histological classification of odontogenic tumours, odontomas originate from odontogenic epithelium and odontogenic ectomesenchyme, with or without hard tissue formation. They are generally classified into two types: complex and compound. Odontomas are usually intraosseous and often associated with delayed eruption of teeth. However, they can be extraosseous and are then referred to as either peripheral complex or compound odontoma. Peripheral odontomas are rare entities. We report a case of an 11 year old boy referred to the Department of Oral and Maxillofacial Surgery, Aarhus University Hospital by the boy's dentist due to fibrous mass in the marginal gingiva in the anterior lower mandible. Removal of the mass revealed a peripheral complex odontoma and at the final 5-month postoperative inspection there was satisfying healing observed, a small, elevated, hyperplastic fibrous marginal gingiva.

Keywords

Odontogenic Tumour, Odontoma, Hamartoma, Complex, Extraosseous, Peripheral

1. Introduction

Odontomas fall within the category of mixed epithelial and mesenchymal odontogenic tumours. The epithelial part gives rise to enamel and the mesenchymal part produces dentin via odontoblast differentiation. They are hamartomas of aborted tooth formation, the definition of a hamartoma is: a tumorlike dysmorphic proliferations of cells native to the organ in which they arise. They gain a

certain size before ceasing their proliferation. They may be expansile but do not invade tissue [1] [2].

Odontomas are classified into: complex and compound. Complex odontomas form an amorphous mass which is unrecognizable as dental tissues compared to the compound type which forms multiple small tooth-like structures which show three separate dental tissues (enamel, dentin and cementum) [1] [2]. Odontomas are one of the most common odontogenic tumours, and usually occur in children and young adults [1] [2] [3]. Odontomas are usually incidental radiographic findings and also found in relation to delayed tooth eruption. They can also cause bone expansion, however they show limited slow growth and are usually asymptomatic [2]. Compound odontomas occur most often in the anterior maxilla while the complex type is more common in the posterior maxilla or mandible [1] [2] [4]. Radiographically, complex odontomas appear with a amorphous mass of calcified material with the radiodensity of a tooth structure, which bears no anatomical resemblance to a tooth surrounded by a narrow radiolucent rim. However, the radiographic appearance depends on the development stage. Three stages exist based on the degree of mineralization [2].

2. Case Report

The patient, an 11-year old boy was referred to the Department of Oral and Maxillofacial Surgery at the University Hospital in Aarhus, Denmark due to a fibrous mass in the labial marginal gingiva of the lower right lateral incisor. The patient was of African ethnicity. He reported that he had been aware of the fibrous mass for at least 2 years and that it had slowly grown in size in that period. He had not noticed any particular bleeding or pain, however it was starting to cause him discomfort during food intake. In regard to his general health and medical history there was nothing specific to report.

Extraoral clinical examination did not reveal any asymmetry. The intraoral examination revealed that the patient was at dental age stage DS4 M1 according to Björk *et al.* 1964 classification [5]. During examination of the patient's soft tissue the fibrous mass in the facial marginal gingiva (**Figure 1**) in relation to the lower right lateral incisor could easily be seen. The mass was broad-based with a firm consistency and the gingival soft tissue showed normal color as well as marginal gingival pocket probing depth of 3 mm. Panoramic and periapical radiographs showed a slight radiopaque, demarcated mass located in relation to the tooth (**Figure 2** and **Figure 3**).

The differential diagnosis according to the clinical and radiographic examination was either a peripheral giant cell granuloma or a peripheral ossifying fibroma.

It was decided to perform an excisional biopsy to determine the definitive diagnosis. There was no suspicion of malignancy. Under local anesthesia, the fibrous mass was removed in whole. It had underlying relation to the facial alveolar bone. The area was left to heal by secondary intention. At follow-up 2

Figure 4. A small, elevated, hyperplastic fibrous marginal gingiva at 5-months postoperatively.

weeks later, the patient described a uneventful postoperative period. A small tooth fragment was found peripherally and was removed, otherwise uneventful healing was seen. At 3-months postoperatively a small area of exposed bone (3×2 mm) was described and finally at 5-months postoperatively a small, elevated, hyperplastic fibrous marginal gingiva was observed (**Figure 4**). The boy was referred back to his own dentist for regular observation.

3. Histology

Macroscopic examination of the specimen showed soft tissue covered by mucosa

measuring at $9.0 \times 8.0 \times 4.0$ mm in size. It had a half-spherical form, which was divided longitudinally and revealed bone like material on the cut surface. The specimen was hard as bone prior to decalcification and moderately indurated after.

Microscopic examination showed at low power view a complex odontoma encapsulated by slightly chronically inflamed dense connective tissue superficially covered by well differentiated slightly parakeratotic squamous epithelium of the oral mucosa (Figure 5). The odontoma was made up of dentin with irregularly oriented pools of enamel matrix and connective tissue (Figure 6). At higher magnification, pulp-like connective tissue with islands of odontogenic epithelium and basophilic cementum-like matrix could easily be detected (Figure 7), as well as dentin with irregular tubule formation and enamel matrix with a few ameloblast-like cells (Figure 8). There were no signs of malignancy and the histological diagnosis was a peripheral complex odontoma.

The histological slides were made after decalcification, where the red dentin and bone/cement matrix (collagen component) were preserved while most of the enamel was dissolved (shown as empty spaces) with a few small rests of enamel which are shown with arrows on the histological slides.

4. Discussion

Intraosseous odontomas are among the most common odontogenic tumours together with ameloblastomas [3] [4]. The peripheral type however, is very rare. That applies both to the compound and complex types, although it seems that the compound type is a bit more common [6]. This makes it quite challenging to make the correct clinical diagnosis. There are many differential diagnoses in relation to an exophytic fibrous mass on the gingiva as in this case report, e.g. peripheral giant cell tumour, peripheral ossifying fibroma, periodontal abscess, gingival hyperplasia etc. [4]. Due to the rarity of extraosseous odontomas, the diagnosis is usually not considered as a differential diagnosis. According to the literature, intraosseous complex odontomas usually arise in the posterior mandible or maxilla [7]. According to previously reported cases [8]-[16] peripheral odontomas have been described to be most prevalent in the incisor/canine region of the maxilla. **Table 1** shows a short review of previous case reports. Another factor that can make it difficult to diagnose is that these entities can be at different stages when it comes to calcification. Three stages have been described [2]. It is not until the third stage that it shows the classical radiographic

Table 1. Summary of clinical and radiological features of previously reported cases of peripheral odontomas, including the present case.

<i>Author</i>	<i>Age (y)/sex</i>	<i>Type</i>	<i>Location</i>	<i>Clinical findings</i>	<i>Radiologic findings</i>
Giunta and Kaplan 1990 [11]	5/F	Compound	Post palatal gingiva	Early rapid growth face, presumed a periodontal abscess	No radiographic appearance
Giunta and Kaplan 1990 [11]	21/M	Compound	Gingiva post mandible	Firm, asymptomatic mass	Diagnosed radiographically in its mature phase
Castro <i>et al.</i> 1994 [12]	6/M	Compound	Upper labial gingiva	Dome-shaped, gingival mass. Pink, firm and asymptomatic. Surface ulceration present	No apparent pathology
Ledesma-Montes <i>et al.</i> 1996 [10]	3/F	Compound	Lingual gingiva mandible	Slow growing, asymptomatic tumour between lower left primary canine and first molar	Nothing remarkable noted
Ide <i>et al.</i> 2000 [15]	39/M	Compound	Upper labial gingiva	Firm gingival, extraosseous mass	Dense radiopaque mass, no evidence of intraosseous lesion
Kintarak <i>et al.</i> 2006 [4]	13/F	Compound	Palatal region	Slow growing, asymptomatic mass between maxillary right central incisor and lateral incisor	No obvious pathology
Bernardes <i>et al.</i> 2008 [16]	12/M	Compound	Upper labial gingiva	Asymptomatic, slightly reddish, firm 4 mm diameter nodule	Not reported
Ide <i>et al.</i> 2008 [8]	7/F	Peripheral developing odontoma	Ant mandible	A gingival nodule with a dimension of 8 mm	Tiny radiopaque mass on the cervical area of lateral incisor
Silva <i>et al.</i> 2009 [14]	8 months/M	Peripheral developing odontoma	Palatal region	Slow growing, asymptomatic congenital nodule	Not reported
Silva <i>et al.</i> 2009 [14]	5 months/M	Peripheral developing odontoma	Palatal region	Asymptomatic, firm nodule	Not reported
Friedrich <i>et al.</i> 2010 [9]	3/M	Peripheral developing odontoma	Palatal region	Asymptomatic, small, firm protrusion	Small radiopaque, extraosseous deposits
Hanemann <i>et al.</i> 2013 [18]	15/F	Compound	Upper labial gingiva	Six small tooth-like structures in the ant left gingiva of the maxilla	Irregular tooth structures composed of crown, root and pulp without bone involvement
Koneru <i>et al.</i> 2014 [13]	15/M	Complex	Labial gingiva ant maxilla	Slow growing, asymptomatic two tiny white nodular masses	No underlying bone resorption and no intra-osseous involvement
Jóhannsson <i>et al.</i> 2017	11/M	Complex	Labial gingiva ant mandible	Fibrous mass in the labial marginal gingiva	Slight radiopaque, demarcated mass in area of lower right lateral incisor

features of the calcified dental tissues. This can make it extremely difficult to identify on a radiographic examination, especially the peripheral type. There also seems to be a lack of consensus in regard to histogenesis of extraosseous odontomas. There are also different theories regarding the specific etiological factors causing the development of extraosseous odontomas, including infection, trauma and genetic factors [17]. In theory, peripheral odontomas may mature over time; eventually erupting into the oral cavity [18]. The clinical characteristics in

this case report did not give a lot of information in regards to a definitive diagnosis other than that it was a slow growing fibrous mass and the radiographic examination did not add further information of any value. Therefore, the need for a biopsy is evident since the differential diagnosis according to the primary clinical and radiographic examination was either a peripheral giant cell granuloma or a peripheral ossifying fibroma.

5. Conclusion

The fact that peripheral odontomas are relatively uncommon, as well the fact that the complex type occurs more seldom than the compound type, makes it hard to diagnose clinically. It can appear as in this case, as a fibrous mass in the marginal gingiva where the thought of a peripheral odontoma does not come first to mind as a differential diagnosis. The fact that they can also arise at different stages of calcification can make it hard to diagnose them on a radiographic examination, as it was in this case report. It was very radiolucent and even hard to detect at a closer look. In light of the aforementioned information, the need for biopsy is clear, since you can only gain so much information from the clinical and radiographical aspects.
